ABSTRACT
The errors that Java programmers are likely to encounter can roughly be categorized into three groups: compile-time (semantic and syntactic), logical, and runtime (exceptions). While much work has focused on the first two, there are very few tools that exist for interpreting the sometimes cryptic messages that result from runtime errors. Novice programmers in particular have difficulty dealing with uncaught exceptions in their code and the resulting stack traces, which are by no means easy to understand. We present Backstop, a tool for debugging runtime errors in Java applications. This tool provides more user-friendly error messages when an uncaught exception occurs, but also provides debugging support by allowing users to watch the execution of the program and the changes to the values of variables. We also present the results of two studies conducted on introductory-level programmers using the two different features of the tool.

1. INTRODUCTION
Despite the availability of many high-quality IDEs and frameworks for developing Java applications, many instructors at the introductory level prefer to focus on the Java language itself, so that students are not overwhelmed by needing to learn both a language and a tool (in addition to algorithmic thinking, data structures, the compilation process, etc). Unfortunately, when left only with the raw Java programming language, tasks such as interpreting stack traces become quite daunting when we consider that the language support for those was not designed with the novice programmer in mind. This leads to frustration for the student, and extra work for the teaching staff, who must spend valuable time explaining the meaning of cryptic Java error messages or debugging techniques that often amount to nothing more than the inclusion of System.out.println statements.

In this paper we present Backstop, a debugging tool designed for programmers studying Java at the introductory level. Backstop produces a detailed and helpful error message when an uncaught runtime error (exception) occurs; it also provides debugging support by displaying the lines of code that are executed as a program runs, as well as the values of any variables on those lines.

Figures 1 and 2 compare the debugging output produced by Backstop and the Java debugger jdb [18], respectively. Backstop shows the changes to the variables in each line, and also displays the values that were used to compute them. Additionally, it does not require the user to enter any commands in order to see that information. On the other hand, jdb only provides “snapshots” of the variable values on demand, without showing the results of individual computations, and requires more user interaction.

2. RELATED WORK
More importantly, when a runtime error occurs, jdb only shows the standard Java stack trace; Backstop displays a more friendly error message with information designed to help the beginning programmer fix the problem (see Figure 3). Unlike jdb, which is very powerful but also very difficult to use, Backstop is a simple application that requires very little input from the user but produces a variety of helpful information that will assist the novice programmer in identifying, debugging, and fixing runtime and logical errors, as well as seeing a running program’s path of execution.

identify the most common compiler errors and provide useful messages around those, but those are pre-processors only and do not provide any runtime support. Although Backstop has some debugging capabilities, it is not intended to be a replacement for visual tools like DDD [17] or JGrasp [19], which are purely front-ends for command-line debuggers and do not address runtime errors.

Some tools have been designed to quickly identify logical errors but not necessarily to resolve them. InSTEP [13] provides an analysis of a student’s running program and can help identify some issues such as an infinite loop or incorrect output, but does not have any tracing facility for seeing intermediate values. DEBUG [11] was written for Pascal and provides analysis of logical errors but does not address runtime errors.

There has also been much investigation of debugging techniques among novice computer science students [1, 12, 15]. Although we are not claiming to provide any new methodology, the tool we present here can be used in conjunction with the approaches in [3], for instance.

The debugging aspect of Backstop is most similar to that of CMeRun [4], which produces a comparable output for C++ programs. However, Backstop includes the handling of runtime error messages, and also provides other advantages such as support for user-defined data types (classes). More importantly, Backstop provides a preprocessor to ensure that the source code is in the appropriate format, whereas CMeRun imposes more restrictions on the formatting of the code.

3. BACKSTOP FEATURES

Backstop consists of two programs that perform the following tasks for helping novice programmers address runtime and logical errors respectively: display error messages concerning uncaught Java exceptions in plain English; and print out the lines of code, including the values of variables, as the lines are executed.

Although Backstop can perform compilation, it is not a compiler: it merely uses the com.sun.tools.javac.Main class. As such, it does not address compile-time errors (semantic and syntactic), and it assumes that the code provided to it will compile. However, given a Java program, Backstop can at once annotate it and encompass it in order to provide debugging support.

Note that in this paper, we use “error” and “exception” interchangeably to refer to any uncaught Java runtime error.

3.1 Interpreting Runtime Errors

The Backstop tool is designed to “catch” any uncaught exceptions. Once the exception (or any other Java runtime error) is caught, Backstop can interpret its meaning and provide a user-friendly message that also seeks to provide some enlightenment as to what caused the error.

A programmer who wants to use Backstop to catch and interpret an uncaught runtime error need only run the Backstop program and provide the name of the (compiled) Java class that contains the “main” method, along with any command-line arguments. Backstop then uses Java reflection to load the class and execute its main method; should any runtime error occur and the ensuing exception is uncaught in the user’s program, Backstop will catch it (it catches anything that extends java.lang.Throwable) and use

the values in the object and its corresponding StackTraceElements to interpret and display information about the exception.

3.1.1 Features

Some information – like the class, method, and line number in which the error occurred – can easily be gleaned from the stack trace, and this information is displayed first. But rather than stating the name of the exception, Backstop tries to explain it in layman’s terms; for instance “The code tried to use an illegal value as an index in an array” instead of “ArrayIndexOutOfBoundsException”, or “The code tried to call a method or refer to a member variable on an object which is null”, instead of “NullPointerException”. Where possible, additional information from the stack trace (such as the value of an out-of-bounds array index) is given in the message as well.

In the case where the source code is available to Backstop (for instance if the source files are in the same directory), Backstop will show the offending line of code and then try to determine (given the context of the exception) what variables may have caused the error. For instance, if the line “foo[x] = 4;” causes an ArrayIndexOutOfBoundsException and the stack trace has the value -2, then Backstop will point out that “the code was trying to access an element at index -2 of the array called ‘foo’” and that “the variable ‘x’ had a value -2 when the error occurred.”

Backstop also provides some assistance to the student as a reminder of how to possibly avoid the same problem in the future. In the above example, it would suggest “Remember, you cannot have a negative index in an array. Be sure the array index is always positive”. For a NullPointerException, Backstop would recommend that the user “may need to initialize the object by using the keyword ‘new’.”

Lastly, so as to relate these exceptions to material that may have been taught in lecture, and so that the student can learn to understand these errors even without Backstop, the type of the exception and the original Java stack trace are presented at the end. Sample output is shown in Figure 3.

3.1.2 Design Considerations

Special care was taken when writing the error messages that would appear to the user. Because the intended audience of this tool consists of introductory-level programmers, we want to ensure that the appearance of an error does not make the student feel “guilty” or as if he or she had done something “wrong”.

```java
An error occurred at line 124 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is:
int blah = Integer.parseInt(arg);

It seems that the code wants to convert a String to an integer.

However, the String "4.5" appears to be a floating point value, not an integer. You may want to use a different datatype to store the value, like float.

This is called a NumberFormatException.

The full error is as follows:
java.lang.NumberFormatException: For input string: "4.5"
at java.lang.NumberFormatException.forInputString(
java.lang.NumberFormatException.java:48)
at java.lang.Integer.parseInt(Java.java:456)
at java.lang.Integer.parseInt(Java.java:497)
at java.main(Java.java:124)

Figure 3. Runtime error as shown by Backstop
```
Therefore, we intentionally avoid wording like “You caused an error” or even “Your code caused an error”, but instead use phrasing like “The code caused an error”, so as to deflect blame away from the student, as recommended in [14].

In addition, in the part of the error message that gives hints as to how to fix the error, we stay away from words like “must” or even “should” (such as “the array index must be positive”), which may come across as pushy and pedantic. Instead, the messages strive for a friendly, more helpful tone, with wording like “don’t forget” or “keep in mind”, which gives the impression that the student already knows these facts.

3.1.3 Limitations
Backstop is designed to specifically handle 22 different types of Java Exceptions and Errors, in particular those that we feel are most likely to be encountered in a CS0 or CS1 course (the full list of errors and corresponding messages is in the appendix). However, when Backstop encounters a Throwable that it does not understand, it will simply print out a message indicating as such, as well as the original stack trace. A future implementation of Backstop could point the user to the online API documentation for the given error.

3.2 Using Backstop to Debug Errors
To aid in the debugging of runtime or even logical errors, Backstop can display the following information for each line of code that is executed: the file name and line number; the code as it is written; and the value of variables in the line (on both sides of an assignment statement, if necessary). This information will help the student see which lines of code are executed, the order of execution, and the values that the different variables are taking on. Most importantly, when a runtime error occurs, the student will be able to see the path of execution that caused the error, as well as the values of all variables at the time of failure.

When used simply as a debugger, the student also has the option of inserting breakpoints into the program in order to step through it instead of seeing all output at once.

Before using Backstop, a student can use its preprocessor to ensure that the source code adheres to the following conventions: each line must contain only one statement; each left and right brace must appear on a line by itself; multiple assignments on the same line are expanded to multiple lines; and, a “case” statement must appear on a line by itself. Students’ code must also ensure that each statement is contained on only one line, and that blocks of code inside loops are surrounded by curly braces (these are not addressed by the preprocessor).

Once the code is in the appropriate format, a student who wants to use Backstop to debug a runtime or logical error (or just to see the execution of the program) starts Backstop and provides the name of the files containing the source code of the Java classes. Backstop then makes backups of the original files and reads the files one line at a time. It copies each line of code and puts a System.out.print command (containing the file name, line number, and code) before the original line of code, and another (containing the values of any variables) after it. These statements are then all written to the new source file. Figure 4 shows an example of code modified by Backstop.

The modified code is then compiled by Backstop, and the original files are restored, so that the programmer can modify that code and does not have to see the code modified by Backstop. However, a copy of the Backstop-modified code is maintained. The programmer then runs the program as normal and would see the debugging output. Sample output is shown in Figure 1 above.

4. USER STUDIES AND EVALUATION
We conducted two studies to measure the usefulness of the two main features of the Backstop application: interpreting and fixing a runtime error, and debugging a logical error. In order to test each feature in isolation, the students were given access to only one of the two parts of Backstop in each study. In testing their ability to fix a runtime error, they were unable to see the debugging output that showed the lines of code as they were executed; in testing their ability to debug a logical error, there was no runtime error for them to look at.

Both studies involved the same group of seventeen students (8 male, 9 female) who at the time of the study had recently completed a CS1 course in Java at Columbia University, but had little or no programming experience besides that. The studies were conducted separately on each student, and were all overseen by the first author of this paper (who was also the students’ instructor in their CS1 course). In each study, the subject was given a task to perform, and we recorded the time to complete the task. Upon
completion of the task, the subject was asked to answer subjective questions about his/her experience.

4.1 Understanding a Runtime Error
In the first task, the students were given a Java program that, for given inputs, would cause a runtime error, resulting in an uncaught exception and termination of the program. The algorithm was first explained to the students, then they were shown the code, and lastly it was demonstrated that an exception would occur for certain inputs. They were then asked to interpret the resulting error message and find and fix the error in the program. In this experiment, we created a control group of four students who did not use Backstop, but only saw the default stack trace produced by Java; the other thirteen students used Backstop.

The program used in this study was to read in a sentence from standard input and display the number of occurrences of each letter in the sentence. However, unbeknownst to the students, the inclusion of any non-alphabetic character (such as a blank space or punctuation) would cause a particular calculation to yield a negative number that – when used as an index to an array – would cause an ArrayIndexOutOfBoundsException. The Backstop error message is shown in Figure 5. All of the students had had that particular exception explained to them in their CS1 course.

```
An error occurred at line 30 of StringCount.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is:
occur[(int)(c - 'a')]++;

It seems that the code tried to use an illegal value as an index in an array.

The code was trying to access an element at index -65 of the array called "occur".
The expression "(int)(c - 'a')" had the value -65 when the error occurred.
Remember, you cannot have a negative index. Be sure that the index is always positive.

This error is called an ArrayIndexOutOfBoundsException.

The full error is as follows:
java.lang.ArrayIndexOutOfBoundsException: -65
at StringCount.main(StringCount.java:30)
```

Figure 5. Backstop output from user study.

Of the thirteen students who used Backstop, nine (76%) were able to identify and fix the cause of the error within eight minutes; the other four could not complete the task within the allotted fifteen minutes. All of the students were able to realize quickly (within two minutes) which calculation was resulting in a negative number, which in turn was causing the exception when used as an array index. The problem some struggled to solve was the issue of “how did this calculation come to produce a negative number?” and they needed to find the answer by debugging the error on their own, since we did not provide them with the debugging functionality of Backstop. Students mainly debugged the problem by inserting System.out.println statements on their own, trying different inputs to see if they could reproduce the error, or thinking about the algorithm. Most likely, of course, the students would have performed better if they had access to the line-by-line debugging output. This particular test is left as future work.

We then asked the thirteen students who had used Backstop questions about the tool. When asked whether they found it “useful”, all of the students said “yes”. When asked whether the output had misled them, two of the students who did not complete the task said that it had, but admitted that they had not read the error message very carefully. We also asked for the students’ comments on the tone of the error message produced by Backstop. Six of the thirteen (46%) claimed that it was “friendly” compared to the stack trace produced by Java. However, four said that the error message was too long, and two more pointed out that anyone but a novice programmer may not appreciate the “pedantic” nature of the message (however, Backstop is indeed targeted to novice programmers). Three of the students said that they did not pay any attention to the tone of the message, but they were merely concerned with getting the appropriate information.

For our control group (who did not use Backstop), we selected four of the top students from the CS1 course. We expected that, even without Backstop and just by looking at the Java stack trace, this group would outperform the other group in terms of the time to complete the task. This proved to be the case, as all four were able to fix the error in under five minutes (one student fixed it in less than two). However, upon seeing the error message produced by Backstop, three of the four said that they probably could have solved the problem faster because they were somewhat confused by the stack trace (the array index that caused the exception is displayed but its meaning is not explained, leading some students to think it was some sort of error code); the only student who said that Backstop may not have helped her claimed that the error message was too long.

Although five of the 17 students said that the error message was too long, we feel that all of the information provided by Backstop is necessary for fixing the runtime error; an alternative suggested by one student is to show only the most crucial information (line number and exception type) and then give the user the option of seeing more (such as the advice for fixing the error).

4.2 Finding a Logical Error
In the next task, all 17 students were asked to find a logical error in a program designed to produce the $n$th Fibonacci number, where $n$ was an argument to the Java program. As in the previous study, the algorithm was explained, the students were shown the code and its output, and lastly it was demonstrated that the output was clearly wrong. They were then asked to use Backstop to debug the code and trace the values of variables in order to see where the logical error had been introduced (we should note that the version of Backstop used in the study did not have the “breakpoint” feature described above; however, the debugging output of the program was small enough to fit into one console window).

The most impressive result of the study was that eight of the 17 students (47%) were able to find the logical error (two lines of code had been juxtaposed) in one minute or less. All of them claimed that the debugging output helped them find the error and that they probably could not have found the error as quickly without the Backstop tool. It bears emphasizing that the students were, in one minute or less, able to find an error in code that they did not originally write.

Of the remaining nine students, five completed the task in five minutes or less, two took six to ten minutes, and two did not complete the task within the fifteen minute time limit. The two students who did not complete the task commented that the
debugging output was hard to read/understand, but said that the output did not hinder them in trying to find the error.

All 17 students were asked questions about their experience at the end of the study. When asked whether the output produced by Backstop was “helpful”, sixteen said “yes”, whereas the only student who did not was one who did not complete the task because he did not understand the output. When asked “did the output mislead you in any way?”, all but five of the students said “no”, though four of the others said “only at first”. The same student who said Backstop was not “helpful” was the same one who claimed to have been misled by the output.

We also asked the students whether there was any other information that could have helped them solve the problem faster. Somewhat surprisingly, five of the students said that it would have been useful for the program to indicate that a logical error had occurred; of course, the program cannot know that a logical error has occurred without knowing what the expected output should be, but the students did not realize that. This indicates that perhaps the students did not fully understand the task, or at least overestimated the tool’s capabilities.

The students were split on their opinions concerning the appearance of the output. Five students (29%) said that more spacing would have helped make it easier to read; however, another four (23%) claimed that more spacing would have made it harder to read. Three (17%) said that the spacing would not make a difference (the remaining students had no opinion).

5. CONCLUSIONS AND FUTURE WORK

We have presented Backstop, a debugging tool targeted at novice and introductory-level Java programmers. The results of our study suggest that it facilitates the interpretation of runtime errors and aids in the debugging of logical errors. The primary contribution of our tool is its ability to make the error messages produced by uncaught Java exceptions easier to understand, and to provide friendlier and more useful information about how to fix the cause of the error. We have also demonstrated that addressing the debugging of runtime errors is necessary and helpful to CS1 students, who clearly could benefit from tools that allow them to understand the cause of such errors and then get assistance in how to fix them.

Backstop could conceivably have been implemented using the Java Platform Debugger Architecture and the IVM Tools Interface, which may provide tighter integration between its two main parts. Additionally, the exception handling feature could be integrated into other debugging and error handling frameworks such as JGrasp [19], or IDEs such as NetBeans [20] and Eclipse [16]. We leave this as future work.

Further studies are necessary to evaluate the usefulness of Backstop, using a larger group of students and by comparing results against other debugging tools like jdb. Additionally, a study needs to be conducted in which the runtime error handling is combined with the debugging feature to see how the students perform when using the combination of tools.

An error occurred at line 37 of Test.java in the method "main".
I'm sorry, the program cannot continue.
The line of code that caused the error is
  list.add("foo");
It appears that the code was trying to call a method or refer to a member
variable on an object called "list", which is null.
Make sure the variable has been initialized in your code.
Remember, declaring the variable isn't the same as initializing it.
You may need to initialize the object using the keyword "new".
This error is called a NullPointerException.

An error occurred at line 42 of Test.java in the method "main".
I'm sorry, the program cannot continue.

The line of code that caused the error is
    int sfs = 5 / 0;

The code was trying to perform an illegal arithmetic operation.
The code has tried to divide by zero, which can't be done, of course!

This error is called an ArithmeticException.

I'm sorry, the program cannot continue.

The line of code that caused the error is
    int c = 5 / (2 - (int)Math.sqrt(ax)) + 4;

The code was trying to perform an illegal arithmetic operation.
It appears as if the expression "(2 - (int)Math.sqrt(ax))" evaluates to zero, but of course you cannot divide by zero. You may want to add some code to check that the expression is not zero before dividing.

This error is called an ArithmeticException.

An error occurred at line 55 of Test.java in the method "main".
I'm sorry, the program cannot continue.

The line of code that caused the error is
    String y = (String)(list.get(0));

It appears that the code tried to cast a variable to the wrong type.

The object you are trying to cast is of type java.lang.Integer. Remember, if you are casting, the object must be the same class as (or a subclass of) the type you are trying to cast to.

This error is called a ClassCastException.

An error occurred at line 61 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is

```java
char cd = "Test".charAt(ax);
```

It appears that the code was trying to access an element at index -5 of the String ""Test"".

Remember, you cannot have a negative index for accessing String characters.

This error is called a `StringIndexOutOfBoundsException`.

The full error is as follows:

```java

An error occurred at line 73 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is

```java
bob.get(-2);
```

It seems that the code tried to use an illegal value as an index to an object.

The code was trying to access an element at index -2 of an array (or other object) on that line.

Remember, you cannot have a negative index. Be sure that the index is always positive.

This error is called an `ArrayIndexOutOfBoundsException`.

The full error is as follows:

An error occurred at line 80 of Test.java in the method "main".
I'm sorry, the program cannot continue.

The line of code that caused the error is
    bob.get(2);

It appears that the code was trying to access an element at index 2. However, the object only has a size of 1, so the biggest index you can have is 0 (remember, the maximum index can only be one less than the size).

This error is called an IndexOutOfBoundsException.

******************************************************************************
*********************************** ERROR **************************************
******************************************************************************
An error occurred at line 93 of Test.java in the method "main".
I'm sorry, the program cannot continue.

The line of code that caused the error is
    int xzx = scan.nextInt();

The code may have been expecting the user to enter an integer. However, the user entered something that was not an integer. Make sure you do not enter a String or a floating-point number. If floating-point values are okay, use a method like nextFloat instead.

This error is called an InputMismatchException.

The full error is as follows:
java.util.InputMismatchException

An error occurred at line 100 of Test.java in the method "main".
I'm sorry, the program cannot continue.

The line of code that caused the error is
```java
xxx = scan.nextInt();
```

The code may have been expecting the user to enter an integer. However, the user entered something that was not an integer. Make sure you do not enter a String or a floating-point number. If floating-point values are okay, use a method like nextFloat instead.

This error is called an InputMismatchException.

The full error is as follows:

```

An error occurred at line 106 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```java
float xxxt = scan.nextFloat();
```

The code may have been expecting the user to enter a floating-point number. However, the user entered something that was not a floating-point number. Make sure you do not enter a String.

This error is called an InputMismatchException.

The full error is as follows:
```java

An error occurred at line 112 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```java
FileInputStream fis = new FileInputStream(f);
```

It appears that the code was trying to operate on a file called foo.txt. However, it seems that you may not have permission to read or write it. Check the permissions of the file and make sure you can read/write it.

This error is called a FileNotFoundException.

The full error is as follows:
```java
java.io.FileNotFoundException: foo.txt (Permission denied)
at java.io.FileInputStream.open(Native Method)
at java.io.FileInputStream.<init>(FileInputStream.java:106)

An error occurred at line 118 of Test.java in the method "main".
I'm sorry, the program cannot continue.

The line of code that caused the error is

```java
fis = new FileInputStream(f);
```

It appears that the code was trying to operate on a file called food.txt. However, it seems that this file may not exist. Check that the filename is spelled correctly and that the path is correct.

This error is called a FileNotFoundException.

The full error is as follows:
```
java.io.FileNotFoundException: food.txt (No such file or directory)
  at java.io.FileInputStream.open(Native Method)
  at java.io.FileInputStream.<init>(FileInputStream.java:106)

An error occurred at line 124 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```
int blah = Integer.parseInt(arg);
```

It seems that the code wants to convert a String to an integer. However, the String "4.5" appears to be a floating point value, not an integer. You may want to use a different datatype to store the value, like float.

This is called a NumberFormatException.

The full error is as follows:
```
java.lang.NumberFormatException: For input string: "4.5"

An error occurred at line 130 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```
blah = Integer.parseInt(arg);
```

It seems that the code wants to convert a String to an integer. However, the String "dog" is non-numeric and cannot be converted.

This is called a NumberFormatException.

The full error is as follows:
```
java.lang.NumberFormatException: For input string: "dog"

An error occurred at line 136 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```java
defloat = Float.parseFloat(arg);
```
It seems that the code tried to convert a String to a floating point value. However, the String "dog" is non-numeric and cannot be converted.

This is called a NumberFormatException.

The full error is as follows:
```
java.langNumberFormatException: For input string: "dog"
    at sun.misc.FloatingDecimal.readJavaFormatString(FloatingDecimal.java:1224)
    at java.lang.Float.parseFloat(Float.java:394)
    at Test.main(Test.java:136)
```
An error occurred at line 142 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```
double ina = Double.parseDouble(null);
```
It appears that the code was trying to convert a String to a number. However, that String was null. Double-check to make sure you have a valid value.

The full error is as follows:
```
java.lang.NullPointerException
    at sun.misc.FloatingDecimal.readJavaFormatString(FloatingDecimal.java:991)
    at java.lang.Double.parseDouble(Double.java:482)

```
An error occurred at line 147 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```
int[] mke = new int[-1];
```
It appears that the code is trying to create an array with a negative size. Remember, the array must have a size that is a positive number.

This error is called a NegativeArraySizeException.

The full error is as follows:
```
java.lang.NegativeArraySizeException
    at Test.main(Test.java:147)
```
An error occurred at line 153 of Test.java in the method "main". I'm sorry, the program cannot continue.

The line of code that caused the error is
```
clvd[0] = new Integer(2);
```
It seems that the code tried to store an object of type java.lang.Integer in an array of Objects that was initialized with a different type.

This is called an ArrayStoreException.

The full error is as follows:
```
java.lang.ArrayStoreException: java.lang.Integer
    at Test.main(Test.java:153)
```
